# Analyzing dynamic data: a tutorial

William Revelle\*, Joshua Wilt

Northwestern University, Evanston, IL Case Western University, Cleveland, OH

#### **Abstract**

Modern data collection techniques allow for intensive measurement within subjects. Analyzing this type of data requires analyzing data at the within subject as well as between subject level. Although sometimes conclusions will be the same at both levels, it is frequently the case that examining within subject data will show much more complex patterns of results than when they are simply aggregated. This tutorial is a simple introduction to the kind of data analytic strategies that are possible using the open source statistical language, R.

Keywords: Open Source, R, Dynamic data, Repeated Measures

The study of personality has traditionally emphasized how people differ from each other and the reliability and validity of these differences. This has been reflected in the many publications in this journal and others emphasizing the structure of personality, scale construction, and validation. The typical data collected emphasized the "R" approach of Cattell's data box (Cattell, 1946a, 1966), that is, correlating how participants differ across items/tests. Cattell's data box also included the possibility of studying how one person varied over time ("P"). Sometimes the approach would consider stabilities across time as measured by the correlation of measures taken at two different time points ("S"). One of the more impressive stabilities is the correlation of .56 over 79 years of IQ scores from age 11 to age 90 (Deary, Pattie, and Starr, 2013). An example of what Cattell referred to as a diagonal in his data box would be the correlation across time of individuals taken on different measures. An powerful example of this would be the prediction of health related outcomes in middle age from teacher ratings of students in grades 1 - 6 (Hampson and Goldberg, 2006).

In the past 30 years or so, we have seen an exciting change in the way we collect data, in that we now can study how individuals vary over time (Cattell's P approach). To Cattell, this was "the method for discovering trait unities" (Cattell, 1946b, p 95). The emphasis is now upon individual variability with the added complexity of how these patterns of individual change differ across participants (e.g., Bolger and Laurenceau, 2013, Mehl and Conner, 2012, Wilt, Funkhouser, and Revelle, 2011, Wilt, Bleidorn, and Revelle, 2016). Although the methods were originally developed to examine data with a nested structure (e.g., students nested within classes nested within schools Bryk and Raudenbush, 1992), the use of these techniques across many occasions within individuals has been labeled *Intensive Longitudinal Methods* (Walls and Schafer, 2006) and "captures life as it is lived" (Bolger, Davis, and Rafaeli, 2003). Analytic strategies for analyzing such multi-level data have been given different names in a variety of fields and are known by a number of different terms such as the random effects or random coefficient models of economics, multi-level models of sociology and psychology, hierarchical linear models of education or more generally, mixed effects models (Fox, 2016). Although frequently cautioned not to do so, some psychologists continue to use a repeated measures analysis of variance approaches rather than the more accurate mixed effects models.

The analysis of data at multiple levels presents at least two challenges, one is that of interpretation, the other is that of statistical inference. It has long been known (Yule, 1903) that relationships found within groups are not necessarily the same as those between groups. Although when aggregating across British health districts, it appeared that increased mortality was associated with increases in vaccinations, when examined at the within district level,

We gratefully acknowldege Aaraon Fisher for making his data set publicly available.

it was clear that vaccinations reduced mortality (Yule, 1912). Variously known as Simpson's paradox (Simpson, 1951), or the ecological fallacy (Robinson, 1950), the observation is that relationships of aggregated data do not imply the same relationship at the disaggregated level. Such results are examples of non-ergodic relationships, that is, relationships that differ from the individual to the group level (Molenaar, 2004, Nesselroade and Molenaar, 2016).

More importantly, when the effect of levels is ignored, structural relationships are difficult to interpret. The correlation between two variables (x and y) when x and y are measured within individuals is a function of the correlation between the individual means ( $r_{xy_{between}}$ ), the pooled within individual correlations ( $r_{xy_{within}}$ ) and the relationships between the data and the between group means  $\eta_{between}$  as well as the the correlation of the data within the within subject means  $\eta_{within}$ .

$$r_{xy} = \eta_{x_{within}} * \eta_{y_{within}} * r_{xy_{within}} + \eta_{x_{between}} * \eta_{y_{between}} * r_{xy_{between}}. \tag{1}$$

Classic examples of this phenomenon other than Yule's vaccination data include bias in graduate admissions as well as effective tax rates. While the overall admissions rate at the University of California suggested a bias against women, when the data were disaggregated and examined at the department level, this effect actually reversed (Bickel, Hammel, and O'Connell, 1975); tax rates can decrease across all income groups even though total taxes increase (Wagner, 1982) as people move into higher income brackets. A very nice discussion of Simpson's paradox and the problem for psychological research is the article by Kievit, Frankenhuis, Waldorp, and Borsboom (2013) and the accompanying software package for R to help diagnose the problem (Kievit and Epskamp, 2012). Simulations to show different between versus within group structures are available in the *psych* package (Revelle, 2017) for R as sim.multilevel and sim.multi.

The second problem of analyzing data at multiple levels is statistical. Multilevel procedures are not part of the traditional training courses for most psychologists. Conventional least squares approaches or analysis of variance are not appropriate for the random effects data typically collected. (By random effects, we mean that the intercepts and slopes may differ for each individual.) But, as more and more personality researchers try to analyze the dynamics of emotion over time and across individuals, texts and tutorials have started appearing. Bolger and Laurenceau (2013) provide an excellent book reviewing methods for analyzing this kind of data and includes examples in four of the standard data processing systems (MPLUS, SPSS, SAS, and R). Of these four, only the last one is not proprietary and advances the concept of open source software. More importantly in this era of conducting reproducible research (Leek and Jager, 2017) R facilitates the dissemination of reproducible statistical code.

If not already, R is well on its way to becoming the lingua franca of statistical analysis. It is open source, free, and extraordinarily powerful. Most importantly, more and more *packages* are being contributed to core R (R Core Team, 2017). As of this writing there are at least 10,000 packages that add to the functionality of R. Given our commitment to open science and the use of open source software, we devote this tutorial to how to use R for simulating and analyzing the intensive longitudinal data that is frequently found in the study of individual differences. We rely heavily on the work of Bolger and Laurenceau (2013) as well as the software manuals for four very powerful R packages (Bates, Mächler, Bolker, and Walker, 2015, Bliese, 2016, Pinheiro, Bates, DebRoy, Sarkar, and R Core Team, 2016, Revelle, 2017). We use a "toy" data set of Shrout and Lane (2012), an open data set released by Fisher (2015), as well as some simulations using the sim.multi function. We emphasize an exploratory data approach using graphical displays and a confirmatory approach using a few of the more commonly used R packages.

What is R and how to use it? R is a data analysis system that is both open source and is also extensible. By open source, we mean that the actual computer code behind all operations is available to anyone to examine and to reuse, within the constraints of the GPL 2.0 (GNU General Public License, 1991). It is free software in the meaning of free speech in that everyone can use it, everyone can examine the code, everyone can distribute it, and everyone can add to it. R may be downloaded for free from the Comprehensive R Archive Network (CRAN which may be found at <a href="https://cran.r-project.org">https://cran.r-project.org</a>) and is available for PCs, MacOS, and Linux/Unix operating systems. For purposes of speed, much of core-R is written in Fortran or C++, but most of the packages for R are written in R itself. For R is more than a statistical system, it is a programming language. This means that R is extensible in that anyone can add packages to the CRAN as well as other repositories such as GitHub or BioConductor (<a href="http://bioconductor.org">http://bioconductor.org</a>). CRAN has certain quality assurance tests that guarantee the contributed programs have consistent documentation, including examples, and will not fail while running these examples. CRAN does not check the validity or utility of

submitted packages, that is up to the contributor as well as the users of the packages. As of this writing, several thousand contributors have added on at least 10,000 *packages* to core-R and this number increases daily.

R was originally developed between 1992 and 1995 by Ross Ihaka and Robert Gentleman at the University of Auckland as a way to implement the S computer language for MacIntosh computers. They were soon joined by others around the world to enhance the development and distribution of R. There are about 20 primary program developers of "Core R" (R Core Team, 2017) who take responsibility for maintaining and distributing the basic system. This is a very eclectic group in that its members come from all over the world.

What makes R so powerful is the programming philosophy of core-R as well as the packages. Rather than give voluminous output for each function, the functions display only the most important aspects of the analysis, and save additional results as elements of the returned object. These objects may then be processed by additional functions. The power of this implementation is that specialized packages can take advantage of the more general core-R features. Thus, the correlation function (cor) can be used by functions that do factor analysis (fa) and the mean function can be used for a function to basic descriptive statistics (describe), which can be combined with the by function to do statistics broken down by groups (describeBy) or be combined again with functions that do correlations, to provide some basic multilevel statistics (statsBy). Without much effort, standard functions such as acv which does ANOVA, or lme to do linear mixed effects models can be integrated into other functions to find, for instance, intra class correlations (ICC) or multilevel reliability (multilevel.reliability). These functions in turn, may be used by the end user by just giving one or two commands. In the appendix to this article, we include the specific commands for example that we give. In the text we prefer to give a more high level summary of the necessary operations. Because there are so many useful texts and web-based tutorials on R it is hard to suggest any particular one. A very short introduction to R is the *Introduction to R* by Venables, Smith, and the R development core team (2017) which is available as a book for a fee, or as a pdf to download from the web for free.

### 1. The basic model

A typical psychological research problem that requires multilevel modeling is the study of how people differ in the pattern of their feelings, thoughts and behaviors over time and place. That people differ is not the question, but rather are these differences systematic and how best to describe them. The analysis could be examining patterns of affect or behavior over time (Fisher, 2015, Fisher and Boswell, 2016), or how people differ in the emotional responses as a function of the situation (Wilt and Revelle, 2017a,b) or how couples relationships change over time (Rubin and Campbell, 2012).

The basic concept of multilevel modeling of dynamics is to decompose variation between individuals and within individuals. While the within individual variability is usually treated as error in conventional analysis of variance, it is this within subject variability that is the essence of multilevel modeling: the analysis of how individuals differ in their pattern of responses over time and how these differences may, in turn, be modeled. For, if we measure individuals over multiple occasions, we can also find the within person mean and variance over time, the within subject correlation of measures over time, and the within person correlation of multiple measures. Thus, we can describe each individual's unique signature over time and space (Hamaker, Ceulemans, Grasman, and Tuerlinckx, 2015, Hamaker, Grasman, and Kamphuis, 2016, Hamaker and Wichers, 2017).

Let **X** represent our data, with an individual observation  $x_{ijk}$  with subscripts i, j, k to represent subjects, measures, and time. We can find the overall mean  $\mu$  and variance  $\sigma^2$ , and decompose these into a function of the within person mean over time for each variable  $\mu_{ij}$  and variance  $\sigma^2_{ij}$ . The *between* subject covariances  $\sigma_{.j_1..j_2}$  represents the covariances of means across subjects (aggregated over time) for measures 1 and 2, and is independent of the *within* subject covariances over time  $\sigma_{ij_1,j_2}$ .

For historical reasons, data at the within subject level are typically called *level 1* data, and data between subjects are known as *level 2* data. This reflects some of the earlier multi-level modelling approaches which show each level as a linear model, with the random coefficients of one level estimated by the higher level model. The models are said to be random coefficients models because the within person parameters (mean and slopes over time for each individual) which are used to estimate the variability within person are themselves coefficients needing to be estimated as characteristics of the subjects.

# 1.1. Preliminary descriptive statistics of a toy model

Consider either the toy example from Shrout and Lane (2012) which has three observations (items) taken at each of four time points for a total of 5 subjects (the data for which are available in the help file for the multilevel.reliabilty function) or one we have created (see Appendix 1) with four subjects measured over six time points on two indicators of each of two factors. The most conventional way to display data is the traditional subjects x variables display seen in Table 1. These data can be "reshaped" using the reshape function into the convenient form seen in Table 3 which is known as a 'wide' format. (As contrasted to Table 1 which might be thought of as super wide or "Fat".) The data are organized into a *data.frame* which is essentially just a two dimensional table of the data. Conventionally, the rows represent subjects and the columns variables. Data frames differ from matrices in that while all the elements of a matrix must be of the same type (e.g., numbers, letters, logical terms), data frames can be mixtures of types, within different columns being of different types.

Table 1: Perhaps the most conventional way of displaying data is one row per subject, with the multiple measures as separate columns. This format does not make it particularly easy for data display or analysis. The data are from the first example set in the Appendix and are displayed in this super wide or 'Fat' format (Table 1). Because of the super wide format, some columns are deleted. Using the reshape function we can convert this Fat format into the more useful Wide format seen in Table 3. Although the simulation that generated the data directly produces the more useful Wide format, we go through this reshape operation for the tutorial value.

A ta	ble from tl	he psych p	ackage in	R							
id	V1.24	V2.24	V3.24	V4.24	V1.48	V2.48	 V4.120	V1.144	V2.144	V3.144	V4.144
1	7	10	4	3	8	7	 5	11	9	1	2
2	6	6	6	5	7	8	 4	8	7	6	6
3	5	6	4	4	6	5	 7	5	4	7	7
4	4	5	4	4	6	4	 3	5	4	4	5

Because it is frequently necessary to reshape Fat to Wide to Long formats, there is a core-R function (reshape) to do this. In addition, a small package (*reshape*) has been added to CRAN, as has a very powerful package, *dplyr* (Wickham and Francois, 2016) for general data manipulation. For simplicity, we use the reshape function and show the results in Table 3. Then, to organize the data.frame by subject id rather than by time, we use the dfOrder function. However, before doing this, we first merge between person trait information into the object.

Many studies of mood or emotion want to relate (level 2) trait measures (e.g., Extraversion, Neuroticism, etc.) with (level 1) daily mood measures. To combine such trait measures with the mood measures is a straight forward application of the merge function. Consider a small data.frame with trait measures for our four subjects (Table 2). We can merge the Xwide object from before with traits to add the trait identifiers to each row. This leads to a somewhat strange form, in that the trait score for each subject is repeated in the data.frame for each of the many rows for each subject. We will do this trick again later when we find mean affect scores for each subject before examining the cross level prediction of trait affect from mean affect (see Section 6).

Table 2: A small data.frame that includes trait information for each subject. This will be merged with the Xwide object from above (not shown) to form a new object, Xwide.traits, shown in (Table 3)

Trait sco	res for the four s	subjects
id	extraversion	neuroticism
1	5	10
2	10	5
3	15	15
4	20	10

Normal descriptive statistics can found for these data by using describe (Table 4) but since we recognize that we are interested in the data by subject, we can also find these statistics by group (subject) using the describeBy function (Table 5).

#### 1.2. Correlations between and within subjects

To examine the correlations between and within subjects, we use the statsBy function which finds the pooled within group correlation, the (weighted) correlation between individual (weighted by the number of observations for

Table 3: Another conventional format when collecting multilevel data is the *wide* format where each variable is a separate column and each time for a subject is a different line. This format allows for statistics aggregating over time. The data were created using the simulation code from the Appendix. Note how the trait information from Table 2 is duplicated for every row for every subject.

Variable	id	time	V1	V2	V3	V4	extrv	nrtcs
1	1	24	7	10	4	3	5	10

V1	3	24	6.17	1.74	6.0	6.10	1.48	3	11	8	0.61	0.44	0.35
V2	4	24	6.17	1.74	6.0	6.05	1.48	4	10	6	0.28	-0.91	0.35
V3	5	24	5.08	1.47	5.0	5.05	1.48	1	9	8	-0.06	1.81	0.30
V4	6	24	4.92	1.50	5.0	5.00	1.48	2	7	5	-0.31	-0.89	0.31
extraversion	7	24	12.50	5.71	12.5	12.50	7.41	5	20	15	0.00	-1.49	1.17
neuroticism	8	24	10.00	3.61	10.0	10.00	3.71	5	15	10	0.00	-1.16	0.74

Table 5: The describeBy function gives basic descriptives for each level of a grouping variable (here the person is the level of the group). Strange data can be detected here by careful examination of the tables. Note that the trait data have no variance within subjects, because they are just duplicate copies of each individual trait scores.

each individual), as well as the separate correlations for each subject. For the toy example, these between subject correlations are not particularly useful, for they are based upon just four subjects. Consider the three different correlation matrices: the normal correlation across all subjects across all time points; the correlations of the subject means (the between groups or individuals correlation); and the pooled correlations within each subject (Table 6). Finally, we can also examine the individual level correlations (Table 7).

Table 6: The overall raw correlations of the Xwide.traits (top matrix) reflects a combination of the pooled within group and the between group correlations as found by the statsBy function. The function returns many different objects, two of which are shown here, rwg for the pooled within group correlations and rbg for the sample size weighted between group correlations, and within for the individual correlations for each subject which is shown in Table 7. Empty cells represent no variance for variables.

Table 7: The correlations for each subject over time are found from the statsBy function and saved as the within object. Note how these within person correlations differ from each other across subjects, and are different from either the raw or the within group (person) correlations shown in Table 6.

# 1.3. Variability over time: Mean Square of Succesive Differences and the Autocorrelation

In addition to correlations of variables over time within and between subjects, variables can also auto-correlate over time with themselves. That is, scores at time t+1 will be related to scores at time t. Emotional states will tend to have this characteristic if measured close enough in time for this is a measure of the stability of the state variable over time. Two related measures can be found to assess this within person variability: The mean square of successive differences (MSSD or  $\delta^2$ ) (von Neumann, Kent, Bellinson, and Hart, 1941) and the auto correlation with lag 1 or  $\rho_1$ . As discussed by Jahng, Wood, and Trull (2008), the MSSD provides a measure of the trial to trial variability which is a more precise indicator of emotional volatility than is the within subject variance. If trials are independent, then the

expected MSSD is just twice the within person variance, but if there are trial to trial dependencies, the MSSD will be much less. The functions mssd and autoR may be used to find these two statistics:

$$\delta^2 = \frac{\sum (x_t - x_{t-1})^2}{N - 1} = 2\sigma_x^2 (1 - \rho_1). \tag{2}$$

# 1.4. Graphical displays

Although we might be able to detect differences in our data by inspection of the means within and between participants, it is very useful to display the data graphically. The function mlPlot calls the xyplot function from the *lattice* package and will plot multilevel data with a separate frame from each subject. We show each subject's data as a function of time and item as a separate panel in such a "lattice" graph (Figure 1). Examining the plot we can see that the two measures for each factor show a high correlation, but that the factors seem to differ in their correlation across subjects. Subject 1 has a strong negative correlation between the two factors, while subject 4 has a strong positive correlation. A plot of real data (from Fisher, 2015) is a an even more impressive demonstration of the power of graphical displays (Figure 2). When examining the auto correlations for those data we see that they are generally positive, implying some day to day stability.

# Lattice Plot by subjects over time

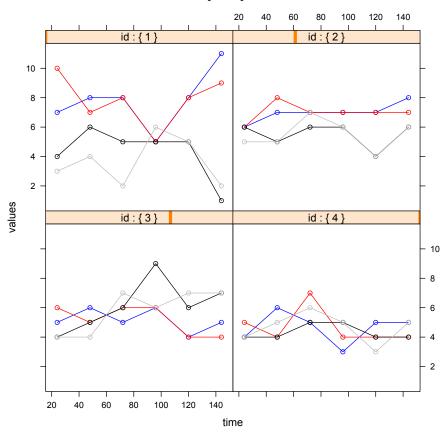

Figure 1: An example of the two dependent measures for two latent factors for four simulated subjects over six time points from Table 3. The within person factor correlations vary from strongly negative to strongly positive although the pooled within correlations are effectively zero. This leads to high positive correlations for variables 1 and 2 and for 3 and 4, although the correlations between these two sets of variables range from highly negative (Subject 1) to highly positive (Subject 4). Compare with the results in Tables 6 and 7.

# 2. Decomposing Reliability: Generalizations over people, over occasions, over items

Traditional reliability measures decompose between person test variance ( $\sigma_x^2$ ) into reliable and un-reliable or error variance ( $\sigma_e^2$ ).

$$\rho_{xx} = \frac{1 - \sigma_e^2}{\sigma_x^2} \tag{3}$$

The problem is then how to find  $\sigma_e^2$ . Solutions include test retest correlations and estimates based upon the internal structure of the test (Guttman, 1945, Revelle and Zinbarg, 2009). Generalizability theory (Gleser, Cronbach, and Rajaratnam, 1965) was developed to solve the problem of multiple sources of variance for each score. This is the situation for multi-level data. For when subjects have scores on multiple items and multiple time points, we are interested in several different indices of reliability. The technique developed by Gleser et al. (1965) was to estimate the variance components using standard ANOVA procedures to find the appropriate Mean Squares for subjects, time, items, etc. and then convert these to variance components based upon the expected values of the MS (Table 8 top part). Taking advantage of the power of R to integrate the output of one function into another, we combine aov, lme and lmer into one function (multilevel.reliability or mlr) which can take wide data, transform it into the long format needed for aov etc., do the analyses, and then find the reliabilities based upon these components and the formulae given by Shrout and Lane (2012). Thus the command to find multilevel reliability for a set of variables is just one line of code rather than the complex expressions necessary in SPSS or SAS (Shrout and Lane, 2012).

Table 8: Analysis of variance may be used on the data to find traditional Sums of Squares and Mean Squares which may be converted to variance components. The example from Shrout and Lane (2012) is converted to long format using mlArrange and then analyzed using the acv function.

```

These mean squares may be converted to variance components using mlr.

	variance	${\tt Percent}$
ID	2.34	0.44
Time	0.38	0.07
Items	0.61	0.11
ID x time	0.92	0.17
${\tt ID}$ x items	0.12	0.02
$\verb time  x items $	0.05	0.01
Residual	0.96	0.18
Total	5.38	1.00

Various reliability (or generalizability) coefficients may be found from these variance components. For instance,

the reliability of individual differences over k fixed time points and m multiple items is

$$R_{kF} = \frac{\sigma_{id}^2 + (\sigma_{idxitems}^2/m)}{\sigma_{id}^2 + (\sigma_{idxitems}^2/m) + \sigma_{error}^2/(km)}$$
(4)

Equation 4 is just one (#6) of the six generalizability coefficients discussed by Shrout and Lane (2012).

Table 9: From the components of variance found in Table 8 we can find a number of generalizability coefficients (Shrout and Lane, 2012). This is all done in the mlr or multilevel.reliability functions.

```
Alternative estimates of reliability based upon Generalizability theory

RkF = 0.97 Reliability of average of all ratings across all items and times (Fixed time effects)

R1R = 0.6 Generalizability of a single time point across all items (Random time effects)

RkR = 0.85 Generalizability of average time points across all items (Random time effects)

Rc = 0.74 Generalizability of change (fixed time points, fixed items)

RkRn = 0.85 Generalizability of between person differences averaged over time (time nested within people)

Rcn = 0.65 Generalizability of within person variations averaged over items (time nested within people)
```

# 3. Types of within subject variation

One purpose of studying multi-level data is to explore individual differences in changes over time. People can differ in their affect as a function of the situation (Wilt and Revelle, 2017b), their scores can increase or decrease over time, and they can show diurnal variation in their moods or their performance. To find the slope over time, we simply apply a within subject regresssion, and to examine the phase and fit of diurnal variation, we use circular statistics (Jammalamadaka and Lund, 2006, Pewsey, Neuhäuser, and Ruxton, 2013) using the cosinor function. In Section 5 we discuss how to generate and analyze simulated data with a variety of data structures, particularly growth and decay over time, and diurnal variation.

### 4. Application to a real data set

In a study of 10 participants diagnosed with clinically generalized anxiety disorder, Fisher (2015) collected 28 items for at least 60 days per participant. In an impressive demonstration of how different people are, Fisher (2015) examined the dynamic factor structure of each person using procedures discussed by Molenaar (1985), Molenaar and Nesselroade (2009). The purpose of the study was to encourage the use of personalized care for clinical psychology. Most importantly, for our purposes, the data set he analyzed is available at Fisher's website (http://www.dynamicpsychlab.com/data) for easy download and subsequent analysis. As discussed in the Appendix, the 10 data files available may be merged into one file and we can examine both the reliability of scales made up of subsets of items, as well as the correlational pattern of these scales. It is important to note that the original paper goes far beyond what we report here, and indeed, the analyses that follow are independent of the main thrust of Fisher's paper. Of the 28 items, we focus on just eight, four measuring general positive affect (happy, content, relaxed, and positive), and four measuring tension and negative affect (angry, afraid, sad, and lonely). We see that the rating suggest a clearly reliable separation between individuals for both positive and negative affects (Table 10). Scoring each subject for these two moods at all time points may done using scoreItems.

The within subject alpha reliabilities and average intercorrelations are found from the mlr function (Table 11). It is important to note that some participants (e,.g. ID002) show much less reliability in the patterning of their scores than others, and that the relationship between positive and negative affect ranges from -.74 to .35. This may be seen clearly in Figure 2.

Table 10: The multilevel.reliablity function estimates of the generalizability coefficients for the positively and negatively valenced items from Fisher (2015). RkF is the reliability of average of all ratings across all items and times (Fixed time effects), R1R is the generalizability of a single time point across all items (Random time effects), RkR is the generalizability of average time points across all items (Random time effects), Rc is the generalizability of change (fixed time points, fixed items), RkRn is the generalizability of between person differences averaged over time (time nested within people) and Rcn is the generalizability of within person variations averaged over items (time nested within people).

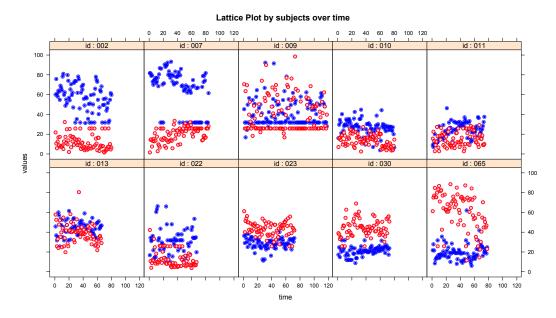

Figure 2: Positive (blue) and negative (red) affect for 10 subjects from the Fisher (2015) data set. Note in particular that subjects 2 and 7 seem to have very high positive affect compared to their negative affects, while subjects 23, 30 and 65 have very low positive affect.

# 5. Simulation as a way to understand within subject data

A very powerful tool in learning how to analyze data and to test how well various models work is to create simulated data set. The sim.multi function allows for creating arbitrarily large data sets with a variety of complex data structures. The basic generator allows one to define a factor model with 1.. f factors with 1.. j items per factor and for 1 .. i subjects and 1 .. k time points. It is possible to define factor loadings globally, or individually for each subject. Factors (and their corresponding items) can increase, remain stable, or decrease over time, and can show diurnal variation with different phase relationships. Diurnal variation is simulated as a sinusoidal curve varying over 24 hours with a peak (phase angle) at different times of day. An example of 16 such subjects is seen in Figure 3 and various summary statistics are given in Table 12. 16 subjects were simulated with two measures taken 8 times a day for six days. The scores for some subjects decreased, while for others they increased over the 6 days. People differ in the strength (amplitude) and phase of their diurnal rhythms. The commands to generate these data are in the appendix.

# 6. Multi-level modeling using nlme and lme4 to detect trait and state effects within and across levels.

The R packages *nlme* (Pinheiro et al., 2016) and *lme4* (Bates et al., 2015) handle a variety of multilevel modeling procedures and can be used to conduct random coefficient modeling (RCM), which is the formal term for models that vary at more than one level. RCM is done in *nlme* with the lme function and in *lme4* with the lmer function. These functions allow for the specification of fixed effects and random effects within and across multiple levels. Therefore, main effects of traits and states can be modeled using these functions, as can random effects of states across traits (or any higher level variables). To do this analysis we first found the mean positive and negative affect for each subject, and then centered these data around the individual's overall mean (*negative.cent*). We see these effects (using lme) and the random coefficients for each individual (extracted using the coef function) for the two variables (positive and negative affect) derived from the Fisher (2015) data set in Table 13. We see that negative emotional *states* lead to lower positive emotions, but that the effect of *trait* negative emotion does not affect state positive affect. The code for producing these models for each multilevel modeling package is given in the Appendix.

Table 12: Various within subject summary statistics of the simulated data including estimates of the phase of the diurnal rhythm, goodness of fit of the diurnal data, between variable correlations with each other and with time of measurement, and the autocorrelation from measure to measure. Summary statistics of data shown in Figure 3. The statistics based upon all subjects are shown on the last line.

# 7. Conclusions

Modern data collection techniques allow for intensive measurement within subjects. Analyzing this type of data requires analyzing data at the within subject as well as between subject level. Although sometimes conclusions will be the same at both levels, it is frequently the case that examining within subject data will show much more complex patterns of results than when they are simply aggregated. This tutorial is a simple introduction to the kind of data analytic strategies that are possible.

# 8. Appendix

Here we show the R code used to do all of the simulations and analysis presented in the article. R itself may be downloaded from the Comprehensive R Archive Network (CRAN) at https://cran.r-project.org. Many people find using RStudio (RStudio Team, 2016) helpful when running R code although our examples do not make use of it. We use several packages psych (Revelle, 2017), lme4, (Bates et al., 2015), and nlme (Pinheiro et al., 2016) that will first need to be installed and then made active. Installing needs to be done once may be done from a menu option or by using the install.packages command. Making selected packages "active" must be done when starting each R session.

# 8.1. Creating the toy example for Section 1.1

We set the random seed to a specific number (e.g., 42, Adams, 1979) in order to produce replicable results. If the seed is not specified, a different pseudo random sequence will be generated for each simulation. The simulation is set to create data for four subjects with two measures (V1 and V2 and V3 and V4) of each of two factors. Items are assumed to have loadings of .6 on one factor, 0 on the other. The factor intercorrelations at the overall level are randomly varying around 0, but differ for each subject, with factor intercorrelations of -.7, 0, 0, and .7 respectively. Although normally we would not round the results of the simulation we do so to create the data in Tables 1 and 3. In addition, the normal output of the sim.multi is already in wide form. We convert it to Fat form and then back again as demonstrations of the reshape and dfOrder functions.

```
R code
library (psych)
                 #activate the psych package
#create the data
set.seed(42)
x <- sim.multi(n.obs=4,nvar=4,nfact=2,days=6,ntrials=6,plot=TRUE,
         phi.i=c(-.7,0,0,.7),loading=.6)
raw <- round(x[3:8])
raw[1:4] <- raw[1:4] +
#make a 'Fat' version
XFat <- reshape(raw,idvar="id",timevar="time",times=1:4,direction="wide")
#show it
XFat
#now make it wide
XWide <- reshape(XFat,idvar="id",varying=2:25,direction="long")</pre>
Xwide <- dfOrder(XWide, "id")</pre>
#add in the trait information
traits <- data.frame(id = 1:4,extraversion =c(5,10,15.20).
                       neuroticism =c(10.5, 15.10))
Xwide.traits <- merge(Xwide,traits, by ="id")</pre>
```

# 8.2. Descriptive statistics

Basic descriptive statistics may be found by using the appropriate functions in the *psych* package. We find overall descriptives (descriptives), descriptives by group (indidividual), and then a variety of multilevel statistics including the pooled within person correlations, the between person correlations, and the individual within individual correlations.

```
R code
#first the overall descriptives
describe (Xwide.traits)
#do it again, but by subjects
describeBy(Xwide.traits, group="id")
#now find the within and between individual correlations
sb <- statsBy(Xwide.traits, group="id",cors=TRUE)</pre>
#show them
                    #top part of Table 6
lowerMat(sb$rwg)
lowerMat(sb$rbg)
                   #lower part of Table 6
round(sb$within,2)
                     #Table 7
#plot the data
mlPlot(Xwide.traits,grp="id",items =3:6)
```

# 8.3. Multilevel reliability using the Shrout and Lane (2012) toy problem

Shrout and Lane (2012) have a toy example for showing reliability calculations. These data are available in the help file for the multilevel.reliability function. Here is how we find the results for Table 8.

#### 8.4. The Fisher data set

R files are downloadable from the http://www.dynamicpsychlab.com/data and unpack as a folder with 10 subfolders. Each of those includes a single R object (e.g., P002.Rdata). Each of these files may be read into R and combined into one larger object. To show the power of R we create a little function to read in the data for a specified directory with a list of names. This could be done by hand for each file, or all together using our new function. After reading the data, it is necessary to scrub the data to change all missing values from 999 to NA. As usual, we use the dim command to see the dimensions of the data and then describe to show over all descriptive statistics.

Get and clean the data.

```
R code
#First create a small function to get the data
'combine.data" <- function(dir=NULL, names) {</pre>
  new <- NULL
  n <- length(names)
  old.dir <- getwd()</pre>
                        #save the current working directory
for (subject in 1:n) {  #repeat n times, once for each subject
 setwd(dir)  #set the working directory to where the files are
x <- read.file(f=paste0(dir,"/P",names[subject],"/pre",names[subject],".csv"))</pre>
 setwd(dir)
  nx <- nrow(x)
   #add id and time to this data frame
  temp <- data.frame(id=names[subject],time=1:nx,x)</pre>
  new <- rbind(new,temp) #combine with prior data.frames to make a longer object
   } #end of the subject loop
 setwd(old.dir)
                  #set the working directory back to the original
                #end the function by returning the data
 return(new)}
#now use this function to read in data from a set of files and
  combine into one data.frame
names <- c("002","007","009","010","011","013","022","023","030","065")
dir="/Users/WR/Downloads/Fisher_2015_Data"
                                                   #specify where the data are
new <- combine.data(dir=dir, names=names)</pre>
fisher <- scrub(new, 2:29, isvalue=999)
                                            #change 999 to NA
dim(fisher) #show the number of rows and columns
describe(fisher) #to see what is there.
```

The data set contains 28 different mood words. For the purpose of the demonstration, we want to find the reliability of four positive affect terms (happy, content, relaxed, and positive) as well as the four negative affect terms (Table 10). We then find scores for all subjects at all time periods by using the scoreItems function. We combine these scores with the id and time information from the original file, and then plot it with the mlPlot function. Finally, to examine the within subject correlations we use the statsBy function with the cors=TRUE option (Table 11).

#### 8.5. Some simulations

We create 16 subjects, with two factors and three items per factor. Simulate data collect 6 times/day over 16 days. We set the random seed to a fixed number for a reproducible example. After generating the data, we apply the cosinor function to estimate the diurnal nature of the signal, statsBy to find the within individual correlations, and autoR to find the auto correlations of the data. We combine the various outputs into one data.frame to display in Table 12.

```
set.seed(17)
x <- sim.multi(n.obs=16,nvar=2,nfact=2,ntrials=48,days=6,
\sin i = c(1,0,0,1), \cos i = c(1,.5,0,-.5), sigma.i = c(0,0,0,0)
sigma=1, phi.i=c(0,0,.5,.5), beta.i=c(-1.,0,1,0,-.5,0,.5,0))
co <- cosinor(x$time,x[3:6],code="id")</pre>
sb <- statsBy(x,group="id",cors=TRUE)</pre>
aR <-autoR(x,group="id")
sim.df \leftarrow data.frame(co[,c(1,2,4,5)],sb$within[,c(8,9,10)],aR$autoR[,3:4])
#to find the pooled data, we do the same analyses,
# but without specifying the group
cos <- cosinor(x$time,x[3:6]) #pooled results
aR <-autoR(x)
                   #pooled results
rs \leftarrow cor(x[3:5])
rs <- rs[lower.tri(rs)]
                           #just use the relevant ones
pooled <- c(cos[1:2,1:2],rs,aR$autoR[3:4])</pre>
#combine the pooled data with the individual data
sim.df <- rbind(sim.df,pooled)</pre>
df2latex(sim.df)
                   #this takes the data.frame and makes it "pretty"
```

# 8.6. Random coefficient modeling using the Fisher data set

We prepare the Fisher data for random coefficient modeling by computing aggregate means (level 2 data) for each participant, merging the level 2 data with the level 1 state data, group-mean centering the state predictor variable around each participant's mean, and merging the centered data. Then we conduct random coefficient models are conducted in the *nlme* package with the lme function and in the *lme4* package with the lmer function. Random coefficients for each participant are extracted with the coef function (Table 13).

```
affect.mean.df <- merge(affect.df,affect.mean.df,by="id")</pre>
#group-mean center positive and negative affect
affect.centered <- affect.mean.df[,c(3,4)] - affect.mean.df[,c(7,8)]</pre>
#rename columns to prepare for merge
colnames(affect.centered) <- c("positive.cent", "negative.cent")</pre>
#add centered variables to data frame
affect.mean.centered <- cbind(affect.mean.df,affect.centered)</pre>
#using the nlme package
library(nlme)
#this model predicts positive affect from time and negative affect (centered),
#and it allows the slopes relating positive affect to time and negative affect
# to vary across participants
pa.na.time.nlme <- lme(positive ~ time + negative.cent + negative.mean</pre>
                                       + negative.cent:negative.mean,
                                       random= ~time + negative.cent|id,
                                      data=affect.mean.centered,
                                      na.action = na.omit)
summary(pa.na.time.nlme) #shows fixed and random effects
#extract the coefficients for each participant
coef.pa.time.nlme <- coef(pa.na.time.nlme)
round(coef.pa.time.nlme,2)
describe (coef.pa.time.nlme) #describe the coefficients
#using the lme4 package
library(lme4)
pa.na.time.lme4 <- lmer(positive ~ time + negative.cent + negative.mean +
                negative.cent:negative.mean + (time|id) + (negative.cent|id),
               data = affect.mean.centered,
               na.action = na.omit)
coef.pa.na.time.lme4
```
